ABSTRACT

Ventriculo-gallbladder shunt is very rarely used in the treatment of hydrocephalus. A 44-year-old male with ventriculooatrial shunt dysfunction was evaluated. His ventriculooatrial shunt was not working. His medical history revealed that his hydrocephalus was treated five times by ventriculoperitoneal shunt, and four times by ventriculooatrial shunt. Another trial for ventriculoperitoneal or ventriculooatrial shunting was not considered feasible. A ventriculo-gallbladder shunt was placed to the patient as a potential salvage procedure. Remarkably, the patient benefited from the ventriculo-gallbladder shunt and was discharged from the hospital. We think that ventriculo-gallbladder shunting is a safe and effective treatment for hydrocephalus as the last resort in complicated cases of shunt dysfunction.

KEYWORDS: Hydrocephalus, Shunt dysfunction, Ventriculo-gallbladder shunt

INTRODUCTION

Ventriculo-peritoneal shunt is the most common method used in the treatment of hydrocephalus (8). When a patient presents with abdominal problems, the ventriculooatrial shunt or ventriculopleural shunt can be considered as a treatment option. Lately, ventriculo-gallbladder shunt has been justified in situations where other options were not possible (4). Herein, we present a case of a patient who did not benefit from multiple ventriculoperitoneal and ventriculooatrial shunt operations, but significantly responded to the ventriculo-gallbladder shunt.

CASE REPORT

A 44-year-old male patient presented with ventriculooatrial shunt infection. His 5-year medical history revealed four ventriculoperitoneal and three ventriculooatrial shunt operations, none of which improved his condition. Although the third ventriculooatrial shunt was functional, it was infected. We replaced the ventriculooatrial shunt with the ventriculo-peritoneal shunt; however, it did not work because of poor absorption capacity in the peritoneal cavity. We assessed the pleural space for placing the ventriculopleural shunt, but the pleura was highly calcified. Therefore, we replaced the ventriculoperitoneal or ventriculooatrial shunting was not considered feasible. A ventriculo-gallbladder shunt was placed to the patient as a potential salvage procedure. Remarkably, the patient benefited from the ventriculo-gallbladder shunt and was discharged from the hospital.

DISCUSSION

Currently, several medical professionals consider the ventriculoperitoneal shunt as the standard treatment of hydrocephalus (8). However, in the case of non-availability...
of the peritoneal space, the ventriculopleural shunt is the most common alternative (5). At times, the ventriculoatrial shunt is also used in the absence of the peritoneal space (7). Nonetheless, in our case, the ventriculo-gallbladder shunt, initially reported by Smith et al.(9), was used as an alternative shunt.

The main function of the gallbladder is to store bile, which is needed for the digestion of food. The liver produces the bile, which then flows through the hepatic ducts into the gallbladder. At any one time, 30–60 mL of bile is stored in the gallbladder. The gallbladder concentrates the bile by absorbing water and inorganic electrolytes; the absorption range is approximately 16% of the total volume of the gallbladder per hour. Whether the cerebrospinal fluid from the gallbladder is drained completely into the duodenum through the common duct or some of it is absorbed by the vesicular epithelium is unclear. The suitability of the gallbladder to absorb the cerebrospinal fluid is because it can resorb fluid and electrolytes, is relatively sterile and the lytic action of the bile can potentially break down proteins in the cerebrospinal fluid, impairing absorption and forming reactive fibrous tissue (9).

The defective absorption of the cerebrospinal fluid through peritoneal and pleural cavities and any contraindication to the ventriculoatrial shunt usage increase the possibility of using the ventriculo-gallbladder shunt. As reported in our case, a majority of patients treated with the ventriculo-gallbladder shunt had an average of 3.9 ventricular shunts of a different type before using the ventriculo-gallbladder shunt (6).

Notably, ultrasonography of the gallbladder and bile ducts and the use of prophylactic antibiotics are necessary for the preparation of the ventriculo-gallbladder shunt. The contraindications to use the ventriculo-gallbladder shunt are cholecystitis, bile duct diseases and intra-abdominal infections. This surgical procedure is easy and well tolerated; however, similar to those in other shunt systems, complications are likely during the post-operative follow-up period. West et al. placed the ventriculo-gallbladder shunt in 25 patients, of whom early (before 2 months) or late infection occurred in 6 patients and gallbladder atony developed in 2 patients (10). Bernstein and Hsueh reported the case of a paediatric patient who died after the application of the ventriculo-gallbladder shunt because of complications such as acquired communicating hydrocephalus, bilious ventriculitis secondary to a ventriculocholecystic shunt and pulmonary oedema (2). Conversely, Barami et al. demonstrated bile reflux in the lumbar-gallbladder shunt placed in a patient, who responded positively to shunt revision (1).

Fountas et al. reported the development of a distal obstruction in a previously inserted ventriculo-gallbladder shunt because of a large, radiolucent bile calculus (3).

■ CONCLUSION

In cases where the peritoneal cavity cannot serve as the insertion site of a ventricular shunt, other body cavities can be used to divert the cerebrospinal fluid. Because the gallbladder is one such alternative, the ventriculo-gallbladder shunt can be utilised successfully.
