Multiple Intracranial Hydatid Cysts in a Boy

Bir Erkek Çocuğunda Birden Fazla Intrakranyal Hidatik Kist

ABSTRACT
Multiple hydatid cysts of the brain are uncommon and may be either primary or secondary. A 15-year-old boy with a huge mass of intracranial hydatid cysts (95x85x80 mm) is presented. The first manifestation was headache and vomiting, which was followed by symptoms of raised intracranial pressure. The patient underwent an urgent operation due to rapidly deteriorating neurological status, and 19 hydatid cysts were removed. Unfortunately, the patient's neurological status did not improve and he died. Hydatid cyst is a benign lesion. Surgery is the standard and most effective treatment for intracranial hydatid cysts. Appropriate and timely management is mandatory for reducing the mortality and morbidity.

KEYWORDS: Brain, Hydatid cyst, Multiple cysts

ÖZ
Beynin multipl hidatik kıstleri seyrek olup primer veya sekonder olabilir. 15 yaşında erkek çocuğunda devasa yer kaplayıcı intrakranyal hidatik kıstlar (95x85x80 mm) sunulmaktadır. Başağrısı ve kusma ilk olarak ortaya çıkmış ve kafa içi basınç artışı bulguları bunları takip etmiştir. Olgu nörolojik durumundaki hızlı kötüleşme nedeniyle acilen ameliyata alındı ve 19 adet hidatik kıst çıkarıldı. Maalesef hastanın nörolojik durumunda düzelve olmadığı ve hasta öldü. Hidatik kıst selim karakterli bir lezyondur. Mortalite ve morbidity için uygun ve zamanında müdahale şarttır.

ANAHTAR SÖZCÜKLER: Beyin, Hidatik kıst, Multipl kıst
INTRODUCTION

Cerebral hydatid disease is rare and occurs in about 2% of cases (35). Hydatid cysts of the brain are usually single, spherical, unilocular, and may be large; in rare instances, they can be multiple and embolic (34). Although an intracranial single lesion is nearly always primary, multiple lesions are frequently secondary (4,5,12,16,19). Multiple hydatid cysts resulting from the rupture of a primary cyst are acephaloceles; they are infertile and have no broad capsule. However, very rarely a multiple larval intake may cause primary multiple cerebral hydatid cysts (3,4,10,19). Intracranial hypertension secondary to mass effect is usually the first clinical sign of brain involvement. Because of their indolent nature, hydatid cysts may not cause focal neurological signs until they are very large (35). They often become significantly larger, particularly in children. In this report, we describe a huge hydatid cyst mass, whose large size had apparently raised the intracranial pressure, causing death.

CASE REPORT

A 15-year-old boy from a rural area was admitted to our neurosurgery department in a state of coma. Neurological examination revealed absence of the pupillary reflex in the right eye. Glasgow Coma Scale (GCS) score was 5 (E=1, M=3, V=1). The patient had been admitted to a hospital in another city with complaints of headache and vomiting four weeks previously. Magnetic resonance imaging (MRI) demonstrated a huge (95x85x80 mm) mass of multiple cystic space-occupying lesions in the right parieto-occipital region, with midline shift to the left hemisphere (Figure 1). The community doctor referred the boy to a neurosurgery clinic with these symptoms.

He was admitted to our emergency service in a state of coma. Patient underwent axial cranial computed tomography (CT) after initial airway and hemodynamic management. CT scan showed multiple hydatid cysts occupying the right parieto-occipital region. No peripheral edema was noted around the cysts (Figure 1). The community doctor referred the boy to a neurosurgery clinic with these symptoms.

An early postoperative follow-up CT scan revealed cyst-free intracranial content (Figure 3). The thorax and abdomen were also observed with CT scans. No lesion was seen on careful examination of the liver, lungs, and other organs. Serological tests for hydatid disease were negative. Eosinophil count was within normal limits. Albendazole was

ranging from 20 mm to 60 mm in diameter were present (Figure 2). The pseudocyst capsule was then completely removed.

Figure 1: MRI of the brain (upper), showing a large mass of multiple cystic space-occupying lesions in the right parieto-occipital region, with midline shift to the left hemisphere. Edema is not seen in the surrounding brain tissue. Cerebral axial CT scan (lower), showing multiple hydatid cysts occupying the right parieto-occipital region with a thinning of occipital bone.

Figure 2: Hydatid cysts and pseudocyst capsule removed at operation.

Figure 3: Cystic masses are not seen on early postoperative control CT scan.
administered to the patient 10 mg/kg twice daily. Unfortunately, the patient’s neurological status did not improve and he died on the sixth postoperative day.

**DISCUSSION**

Cerebral cystic echinococcosis is seen in approximately 2% of patients infected with the parasite and this represents only 2% of all intracranial space-occupying lesions. It is most commonly seen in children and young adults (approximately 50–70%) (9,35).

Multiple hydatid cysts of the brain are very rare. Primary multiple cysts of the brain resulting from arterial embolism secondary to ingestion of multiple larvae and without any radiological or clinical evidence of hydatid disease elsewhere in the body are extremely rare (3,4,10,13,18,19,20,25,26,29,30,31,32,33,34,37,39). In a review of the literature related to primary multiple intracranial cerebral hydatid cysts, we were able to find only 17 cases reported up to the time of preparing this article (Table I). Secondary multiple hydatid cysts of the brain can result from spontaneous, traumatic, or surgical rupture of a primary solitary cerebral cyst or as a consequence of a cyst rupture elsewhere and embolization of hydatids to the brain (14,15,21,38). Multiple hydatid cysts resulting from the rupture of a primary cyst are acephaloceles; they are infertile and have no broad capsule and scolecis (2,4,5). The growth rate of cerebral hydatid cysts is 1 cm in diameter per year. This rate, however, may be more rapid in children (1,4,9,16,18,35).

Headache and vomiting and, motor weakness due to increased intracranial pressure are the most common clinical manifestations of hydatid disease (22,28). Headache is usually the earliest symptom. The serologic tests are of little practical value in confirming the diagnosis of cerebral echinococcal disease (22,28). The results of both of Casoni and Weinberg tests were also negative in our patient. CT scan and MRI are excellent techniques to diagnose and localize the lesions (1,5,6,18,23,24,27,40).

Surgery is the standard and most effective treatment for intracranial hydatid cysts. The aim of surgery is to remove the cysts without rupture. The preoperative diagnosis is very important both in planning the surgery and taking the measures against spillage of daughter cysts and scolices at surgery. Rupture is associated with the well-recognized problems of anaphylaxis, meningitis, or local recurrence from spillage of the cyst contents (1,8,17,22).

The cavity remaining after the removal of large space-occupying cysts may cause serious complications, such as cortical collapse, cerebral edema, hyperpyrexia, cardiorespiratory failure or subdural hematomas in the early postoperative days. The development of subdural collections and porencephalic cyst has also been reported in the late postoperative days (15,36). The mortality rate of porencephalic cyst has also been reported in the late postoperative days. The development of subdural collections and porencephalic cyst has also been reported in the late postoperative days.

Nevertheless, hydatid cyst is a benign lesion. Appropriate and timely management is mandatory for reducing mortality and morbidity.
